Abstract

Background

Higher levels of religiousness are associated with better mental health outcomes, but most of previous research is cross-sectional, failing to address issues of selection and reverse causation.

Methods

We assessed the longitudinal association between both public and private religiousness and depressive symptoms, drawing on data from 7,719 persons aged 65 and older of the Survey of Health, Ageing and Retirement in Europe (SHARE). Repeated measurements of different aspects of religiousness and depressive symptoms were used in random and fixed-effects models in order to assess the effect of changes in religious behavior on changes in depressive symptoms.

Results

Praying more than once a day was associated with more depressive symptoms (β = 0.150, 95% CI: 0.003, 0.298) relative to individuals who never pray, adjusted for socio-demographic, physical health covariates and history of depression, but the comparison with the fixed effects model suggests that this is the result of a selection effect. Participating weekly or more in a religious organization was associated with fewer depressive symptoms (β = -0.219, 95% CI: -0.344, -0.094), but this appeared to be spurious after taking due account of possible confounders (β = -0.092, 95% CI: -0.223, 0.038). Focusing on within-persons changes, we found that participating in religious organizations weekly or more was associated with more depressive symptoms (β = 0.275, 95% CI: 0.075, 0.475).

Conclusion

Our findings do not support that religious behavior, both public or private, may be beneficial for the mental health of older Europeans.
Introduction

Depression is among the most prevalent mental disorders in middle and high income countries and it is ranked as the leading cause of disability worldwide [1]. With a rapidly ageing population, depression amongst the elderly is therefore an important global public health concern. While old age can be a time of well-deserved rest with more spare time to spend with family, to engage in social and cultural activities and to enjoy life after all those working years, unfortunately it is often accompanied with a variety of challenges which are associated with depression: loneliness, poor social support, disability, deteriorating health, financial strains and poverty [2-4]. Depression is associated with decreased well-being and negative health outcomes, such as suicide [5] and cardiac disease [6]. For that reason, understanding the social origins of depressive symptoms is of utmost importance for public policies to be effective in improving quality of life in old age.

One of such social determinants is religious participation. The majority of previous research suggests fairly consistent yet modest protective effects of religious participation on depression, especially for religious service attendance [7-11]. This inverse association can be explained through two different pathways. First, religion as a personal practice, such as praying, might be a way to cope with stress, in turn reducing the likelihood that stress will develop into depressive symptoms. At some point in later life, stressful life-events are likely to happen, like sickness, the loss of a loved one, or changes in one’s financial situation due to retirement. Given the higher frequency of occurrence of such life events in old age, religion as a personal practice may be of particular importance to the elderly [12]. Second, religion as a public activity provides social support through the communities of religious groups [13]. The support offered by these social groups can be understood as individuals who share the same interests, values and norms [14], or who assist each other with tasks, or financial assistance [12]. As social support is found to be an important condition of mental health and well-being, particularly for the older and retired population [15-17], participating in religious activities or communities might affect the risk of depression and depressive symptoms in a beneficial way. As such, religiousness as both a public social support and a personal coping strategy is an important element in the study of the social origins of mental ill-health.

Yet, studies that apply such multidimensional construct of religiosity find that particular forms of religiosity are associated with higher levels or incidence of depressive symptoms at old age [18-23]. It is mostly communal forms of religious participation rather than merely private
practices, which are found to be protective against mental ill-health [8,9]. Therefore, it’s essential to distinguish between different aspects of religiosity, since different dimensions can affect depressive symptoms at old age in different and possibly contradictory ways.

The main limitation in the current body of research on religiousness and depression is that the majority of studies are cross-sectional [9] and thus based on measures at only one point in time or without control for baseline depression. However, prior depression can affect subsequent religious behavior, which means that an inverse relationship between religious service attendance and depression can be the result of depressed individuals stopping religious service attendance, and not because service attendance protects against depression [24,25]. Evidence for such reverse causality is provided by Maselko et al. [24]. They find that women diagnosed with depression before age 18 were more likely to stop attending religious services in early adulthood, compared to women with adult-onset depression or no lifetime depression. Li et al. [26] find that women suffering from depression were less likely to subsequently attend religious services once or more per week four years later, compared to women who were not depressed in the past. This issue of reverse causation cannot be addressed based on data collected at a single point in time.

The small proportion of studies that did use longitudinal data to assess associations between religiousness and depression find protective effects of service attendance on depression in the United States (US). [26-29], but much less is known about the association outside the US. [30]. Ahrenfeldt et al. [8] examine the association between religiousness and health in 9 European countries. They find that participants who reported praying, took part in a religious organization, and were religiously educated had lower depressive symptoms compared to respondents who only prayed or were non-religious. Building upon that, they distinguish two patterns of religiosity i.e. restful religiousness (praying, taking part in a religious organization and being religiously educated) and crisis religiousness (only praying), which are suggested to influence health in different ways. The former is thought to be associated with good health, while the latter is thought to be associated with poor health.

This article expands the current literature on depression and religiousness in Europe by assessing the longitudinal association between different aspects of religiousness and depressive symptoms among elderly in Europe. In doing so, we expand the dominant cross-sectional between-persons approach in the current research on religiousness and depression with a
longitudinal within-persons approach, as both religiousness and depressive symptoms are not fixed states, but characteristics changing over time, possibly in a causal way.

**Methods**

**Sample**

We draw data from the Survey of Health, Ageing and Retirement in Europe (SHARE) [31]. SHARE is a representative dataset of individuals aged 50 and older in 19 European countries and Israel. SHARE includes microdata on the socio-economic status and health status, both physical and mental, and allows the cross-national comparison of health indicators as well as the analysis of the determinants of health over time [4]. We select respondents aged 65 and older who entered the survey in wave 1 (2004-2005) and were followed-up in at least one subsequent wave (wave 2 (2006-2007), 4 (2011) or 5 (2013)). Wave 3 does not assess depressive symptoms or religiousness and is therefore excluded from the analyses. We include respondents with no missing values of depressive symptoms and religiousness at wave 1 (n = 7,719). This sample includes participants come from Austria, Germany, Sweden, Netherlands, Spain, Italy, Denmark, Greece, Switzerland, Belgium and Israel.

**Measures**

**Assessment of depressive symptoms**

Depressive symptoms are repeatedly measured by means of the EURO-D scale in all four waves. This measurement of depression was developed by Prince et al. [32] and is a widely used validated indicator of late-life depression [33]. The score range is 0-12, with higher scores indicating higher levels of depressive symptoms. A threshold of 4 or above is used to indicate a clinically significant depression.

**Religiousness**

Religiosity is multidimensional and different aspects of religion may be associated with depression in a different way. Therefore, three measures of religiousness will be included in our models. The first two are repeatedly measured across all four waves, which allows us to assess the effect of changes in religious behavior on depressive symptoms. First, the public aspect of religiousness is measured by the question “Have you done any of these activities in the past month?: Taken part in a religious organization (church, synagogue, mosque, etc.)”. In
waves 4 and 5, the question changed from how often in the past month participants had engaged in such activity to the past year. Answers on this question included the additional option of “less than every month”. Responses are coded zero for ‘Not participating or less than monthly’ and one for ‘Participating almost weekly or more’. Second, praying was assessed by the question “Thinking about the present, how often do you pray?” and captures the personal aspect of religious involvement. We categorized responses into never, less often than weekly, weekly or a couple of times a week, daily and more than once a day. Third, religious education was assessed only when entering the survey by the question “Have you been educated religiously by your parents?”.

**Socio-demographic and health controls**

We include three time constant covariates, namely gender, and educational level. Highest educational level is grouped according to the International Standard Classification of Education [34] into primary school (classifications 0-1); lower secondary (classification 2); higher secondary (classifications 3-4); and tertiary education (classifications 5-6). The set of time-varying covariates which are all repeatedly measured across all four waves includes age, marital status, economic strain, four measures of physical health and info on personal depression history. Age is categorized in three age groups: 65-74, 75-79, 80-84 and 85 years old or older. Marital status is grouped in married, divorced/separated/never married, and widowed. Economic strain is a subjective indicator of financial distress (“Thinking of your household's total monthly income, would you say that your household is able to make ends meet?”), dichotomized into ‘with difficulties’, and ‘easily’. The first indicator of physical health status is a binary variable indicating whether an individual reports at least one limitation in activities of daily living (ADL). These activities comprise tasks that are necessary for personal care, like showering and self-feeding. Second, a variable indicating whether a respondent reports at least one limitation in instrumental activities of daily living (IADL). These are tasks essential to maintain a living environment, such as shopping for groceries and preparing a hot meal. Third, self-rated health was assessed by a generic question dichotomized into good versus poor. Fourth, long-term health problems are assessed by respondents indicating whether they have any long-term health problems, illness, disability or infirmity. Finally, personal history of depression is assessed by questions on whether the respondent ever suffered from a major depression.
Statistical methods

In OLS regression it is assumed that the observations in the sample are independent of each other. However, the same respondents contribute two or more records to our dataset which makes a direct application of OLS to our data inappropriate. To solve this dependence problem, we analyze the changes in depressive symptoms over time and explore the effects of time-varying measures of religiousness on individual depression outcomes by means of random and fixed-effects models. This way, the total number of waves is allowed to vary among respondents and respondents who are not surveyed in all waves are retained in the analyses. First, we estimate random effects models to estimate the effect of religiosity on depressive symptoms. Random effects models assume that unobserved differences between individuals that are constant over time are random [35], and allow us to assess the effects of both time-varying and time-constant variables.

The second specification is based on individual fixed-effects regressions which use within-individual changes in religiousness while controlling for all measured and unmeasured time-invariant confounders that differ across individuals [36,37]. An appealing feature of a fixed effects model is that the coefficient estimates are not biased by measured or unmeasured time-invariant confounders, such as genetic differences and personality traits, which may play an essential role in the relation between religiosity and mental health. Failure to control for such characteristics may yield biased estimations of the observed association. Our fixed effects models can be expressed as

\[ y_{it} = \beta_0 + \beta_1 x_{it} + \beta_2 z_{it} + \alpha_i + \varepsilon_{it} \quad (1) \]

where \( y_{it} \) indicates the score on the depression scale for individual \( i \) at wave \( t \). A set of measurements of religiousness (i.e. participating in a religious organization and frequency of praying) which varies over time is represented by the vector \( x_{it} \) and a set of time-varying control variables \( z_{it} \) with each set their respective coefficients \( \beta_1 \) and \( \beta_2 \). Coefficient \( \alpha_i \) is treated as a constant effect, which controls for time-invariant individual characteristics, and \( \varepsilon_{it} \) is the within-individual error term. The key distinction between the random and fixed effects model is whether \( \alpha_i \) is assumed to be correlated with the other covariates in the model. In a random effects model, \( \alpha_i \) is assumed to be independent of the other covariates, while in a fixed effects model \( \alpha_i \) represents the unmeasured confounding [37].
We follow a stepwise approach to build the models, starting with models that control for age and wave only. We then incorporate time-varying, which includes marital status, financial situation, ADL, IADL, self-rated health, suffering from a long-term health problem, history of depression, and time-constant controls, which includes gender, educational level and being religiously educated. We estimate individual clustered robust standard errors for all estimates. All analyses are conducted using Stata version 15.1 (StataCorp LG, College Station, Texas). The code supporting this article is available upon request from the authors.

Results

Sample baseline characteristics are summarized in Table 1. The mean number of depressive symptoms is 2.45 (SD = 2.31) with 26.7% of the respondents reporting a score ≥ 4, indicating a clinical depression. The vast majority of respondents (88.8%) does not participate in a religious organization or does so less than monthly. In terms of praying, 27.4% never prays, 15.4% prays less often than weekly, 19.2% weekly or a couple of times a week, 21.9% daily and 16.1% prays more than once a day. The mean age is 71 (SD = 6.35). The majority of our respondents are Catholic (43.9%) or Protestant (26.4%). Only 0.8% is Muslim, and 6.7% is Jewish. 10.3% stated that they do not belong or feel attached to a religion. Approximately 46.9% of the respondents are men, 56.5% suffers from a long-term health problem, and 25.3% is widowed. It is important to note that religiousness varies across countries. Public religious participation levels are generally higher in Greece, Israel and Austria with respectively 31.3%, 14.7% and 11.6% of the respondents participating at least weekly or daily in a religious organization. Praying at least once a day is more common in Greece (62.0%), Italy (53.7%) and Switzerland (48.5%). Italy (97.5%), Greece (95.0%) and Spain (95.3%) have the highest percentage of respondents being religiously educated. Mean depression scores vary among countries as well. In Spain, the mean score on the depression scale was 3.71 (SD = 2.81) which makes it the country with the highest mean depression score, followed by Israel (2.99, SD = 2.66) and Italy (2.84, SD = 2.42).

- Higher secondary (ISCED 3-4) | 2000 26.1 |
- Tertiary education (ISCED 5-6) | 1058 13.8 |
- Having difficulties to make ends meet | 2120 38.2 |

**Abbreviations:** ADL, activities of daily living; EURO-D, depression symptoms scale running from 0 to 12; IADL, instrumental activities of daily living; ISCED, International Standard Classification of Education.

<sup>a</sup>Expressed as mean values (standard deviations).

<sup>b</sup>Sample sizes vary due to missing values for ‘Having difficulties to make ends meet’ (n = 5,547), educational level (n = 7,656), and self-rated health (n=7,697).
The estimates of model 1 (Table 2) show that participation in religious organizations ($\beta = -0.219$, 95% CI: -0.344, -0.094) is significantly associated with fewer depressive symptoms, after adjusting for age and survey wave. Praying daily ($\beta = 0.428$, 95% CI: 0.303, 0.554) and more than once a day ($\beta = 0.588$, 95% CI: 0.445, 0.731) are associated with a higher score on the depression scale. Results of model 2 show that being a woman ($\beta = 0.463$, 95% CI: 0.362, 0.564), widowed ($\beta = 0.285$, 95% CI: 0.165, 0.404), having financial difficulties ($\beta = 0.488$, 95% CI: 0.387, 0.588), limitations in activities of daily living ($\beta = 0.811$, 95% CI: 0.657, 0.964), limitations in instrumental activities of daily living ($\beta = 0.895$, 95% CI: 0.774, 1.015), long-term health problems ($\beta = 0.399$, 95% CI: 0.313, 0.484), poor self-reported health ($\beta = 0.479$, 95% CI: 0.391, 0.567), and having suffered from depression in the past ($\beta = 1.201$, 95% CI: 1.083, 1.320) are all associated with higher levels of depressive symptoms. Focusing on the measures of religiosity, we see that public religious involvement is not significantly associated anymore with fewer depressive symptoms ($\beta = -0.092$, 95% CI: -0.223, 0.039). The private aspect of religiosity, praying more than once a day ($\beta = 0.150$, 95% CI: 0.003, 0.298) is significantly associated with more depressive symptoms, after controlling for several socio-demographic and health controls, history of depression, country, and survey wave.

Results from the fixed-effects models are presented in Table 3. Here, we control for unobserved individual heterogeneity that may be correlated with our explanatory variables. Model 3 only controls for age and survey wave. The results show that changes in public (β = 0.097, 95% CI: -0.082, 0.275) and private (β = 0.124, 95% CI: -0.122, 0.370) religious involvement are not significantly associated with changes in depressive symptoms. In model 4, we see that public religiousness (β = 0.275, 95% CI: 0.075, 0.475) is significantly related to more depressive symptoms. No significant effects are found for private religious involvement (β = -0.173, 95% CI: -0.471, 0.124). Furthermore, changes in financial difficulties (β = 0.239, 95% CI: 0.068, 0.410), activity limitations in daily living (β = 0.452, 95% CI: 0.201, 0.703), limitations in instrumental activities of daily living (β = 0.692, 95% CI: 0.509, 0.874), and self-rated health (β = 0.157, 95% CI: 0.019, 0.295), and suffered from a depression in the past (β = 0.622, 95% CI: 0.443, 0.801) are associated with increases in depressive symptoms.

Discussion

This study adds to the scarce longitudinal evidence of religiousness and its effects on depression using data from 11 European countries. Our findings confirm that religious behavior is associated with depressive symptoms in old age and that the strength and direction of this association varies among different aspects of religiosity. The results of our random effects models show that participation in religious organizations (public religious involvement) is associated with fewer depressive symptoms, while higher frequency of praying (private religious practice) is associated with higher levels of depressive symptoms. However, the protective effect of public religious involvement vanishes when we take due account of possible confounders (financial difficulties, sex, ill health, disability, education, country and personal history of depression), suggesting a spurious relationship. For example, respondents who less frequently attend a church service report higher levels of depressive symptoms merely due to health problems, or because they suffered from a depression in the past. Furthermore, we find that sex, educational level, perceived financial situation and physical health all significantly affect depressive symptoms.
A key challenge in this field of research is selection: is the association between religiousness and mental health the result of religiousness influencing mental health, or are there unobserved characteristics that may confound their relationship? We attempt to address this issue by means of fixed-effects modelling which accounts for all time-constant characteristics that may influence the association between religiosity and depressive symptoms, without explicitly measuring them. This ensures that our estimates are not biased by time-invariant confounders such as genetic differences and personality traits, which may play an essential role in the relation between religiosity and mental health. Focusing on within-person variation, we find that changes in public religious behavior predict changes in depressive symptoms in a positive way, with higher levels of church attendance predicting higher levels of depressive symptoms. This finding seems counter-intuitive with previous longitudinal research on religiousness and depression in the U.S. [26-29]. It might be that in Europe, public religious participation is losing its significance, due to increasing religious individualization [38], which might explain our contradictory findings. In that case, merely participating in these activities may not be sufficient to benefit from the social support offered by religious organizations. It may be necessary to be a “true believer” [39] or to be “more religious” [8] and internalize religious meanings and values also privately, and not solely by attending religious services. Yet, no significant effect is found for praying when looking at within-persons variations in praying behavior, which is in contrast with the results of our random effects model but in line with previous research suggesting much weaker or no associations between private practice measures of religiosity and health [30]. The different estimates of the private aspect of religiosity between the random effects and fixed-effects approaches suggest a selection effect i.e. individuals with higher scores on the depression scale are more likely to pray multiple times a day, and continue to do so, compared with less depressed respondents. It is plausible that prolonged reliance on prayer may lead to neglecting professional help, which subsequently leads to rising levels of depressive symptoms. However, we have no evidence that changes in praying behavior are accompanied by changes in the number of depressive symptoms.

Our study has several advantages over the current state of the literature. First, we use a large, representative, longitudinal sample of older Europeans, as many of the studies on religiousness and old age depression are based on unrepresentative sample, which for example, include only older adults treated in a mental health [20, 21] or clinical setting [40], or focus on the U.S. [10] like the majority of the research on depression and religiousness [30]. Second, we have repeated measures on participation in religious organizations and frequency of praying, in
addition to information on whether the respondent was religiously educated, which we considered simultaneously, as these different aspects of religiosity are found to affect depression in different ways [8, 10, 41]. Third, most evidence for the relationship between religiosity and depression is based on cross-sectional designs, precluding causal inference [9].

Using fixed and random effects models, we are able to study specifically the effect of changes in religiosity on changes in depressive symptoms. To date, the issue of which estimator is preferred for survey panel models has not been fully resolved yet. The choice of model is usually assessed by means of the Hausman test, which tests whether the individual-specific fixed-effects modelled in random effects are correlated with the exposure variables [42]. We rejected the null hypothesis that they are not, which makes a fixed-effects model more appropriate. However, the outcome of the Hausman test is not the only aspect to take into account when choosing the appropriate model. In the context of mental health and depression, we cannot be sure that the model we are testing includes all variables that are likely to jointly influence depression and religious involvement. It is plausible that some omitted sources of variation in depressive symptoms correlate with our predictors which makes a fixed-effects model preferable as well. Variables like genetics or personal characteristics, are difficult to measure and can, when not included in the model, produce a specification error in a random effects model [35,36]. We see the use of both methods as a contribution to the research on depressive symptoms and religiousness at old age, as with the random effects models we are able to estimate the effects of time constant characteristics, while the fixed effects models accounts for all unmeasured time constant confounding.

Some limitations should be acknowledged. While we do control for unmeasured time-constant confounding in our fixed effects models, unmeasured time-varying confounding remains a potential source of bias. Therefore the estimates may not be interpreted as causal. Changes in religiousness may be correlated with changes in other variables associated with depressive symptoms. For example, older persons may increase their religious involvement after the occurrence of certain life-events, such as the death of a relative, or the birth of a grandchild. Additionally, in a fixed effects model, the current values of the error term are prohibited to be correlated with past, present and future values of the independent variables [37]. However if current scores on the depression scale affect future religious behavior, the error term is necessarily correlated with future religiousness. This assumption of strict exogeneity can be problematic as individuals suffering from a major depressive disorder are found to be more likely to subsequently stop attending religious services [24,26]. Although we addressed this by
controlling for history of depression, the possibility of reverse causation cannot be fully ruled out in a fixed effect setting.

This study extends prior rigorous research on the relationship between depressive symptoms and religious involvement in old age by assessing their longitudinal relationship in a representative sample of older Europeans. Our analyses demonstrate that public and individual religious involvement are associated with depressive symptoms, but in different ways. Public religious involvement measured as participation in religious activities is associated with fewer depressive symptoms, but this relationship appears to be spurious. When focusing on within-persons changes, we find that changes in church attendance are associated with higher levels of depressive symptoms, even after controlling for changes in health and financial status, history of depression and all time-constant characteristics. Regarding private religious involvement, praying is associated with more depressive symptoms. Yet, our findings suggest that this is due to a selection effect. Our findings do not provide evidence that public policy and healthcare interventions to support religious behavior, both public or private, are effective in reducing depressive symptoms in old age.
